17 December 2017

Introduction

This year, on October 18, 2017, Law Enforcement Leaders urged Attorney General Jeff Sessions to reconsider his stance on reverting back to “overly punitive” approaches of the 1980s and 1990s to reduce crime. Since President Trump believes that America is in the midst of a national crime wave, Sessions thought a more conservative approach of deterrence through arrests, incapacitation through imprisonment, harsh sentencing and higher police per capita would lead to lower crime rates overall. However, police chiefs who have first hand decades of experience on the front lines learned that these tactics are ineffective to reduce crime.

In this paper, we will explore whether the conservative approach to crime effectively reduce crime rates. We began by exploring North Carolina’s crime dataset of 1988 when “overly punitive” approaches of the 1980s and 1990s would have taken place and analyzed the determinants of crime based on the research question: Does the conservative approach of deterrence through arrests, incapacitation through imprisonment, harsh sentencing and higher police per capita lead to lower crime rates? We will list out the limitations of our analysis, including any estimates that suffer from endogeneity bias, and generate policy suggestions based on our findings.

Exploratory Data Analysis

```
# load the data
data <- read.csv("crime_v2_updated.csv")
# verify that it only contains data from 1988
unique(data$year)

## [1] 88

# list number of counties
length(unique(data$county))

## [1] 90

# list number of western, central, and urban counties
c(sum(data$west == 1), sum(data$central == 1), sum(data$urban == 1))

## [1] 34 21 8

# list number of western & urban counties and central & urban counties
c(sum(data$west == 1 & data$urban == 1), sum(data$central == 1 & data$urban == 1))

## [1] 5 1

# verify number of missing values
colSums(sapply(data, is.na))

##      X   county   year   crime  probarr  probsen  probconv  avgsen
##      0      0      0      0      0      0      0      0
## police density   tax    west  central   urban  pctmin  wagecon
##      0      0      0      0      0      0      0      0
```

```
##   wagetuc   wagetrd   wagefir   wageser   wagemfg   wagefed   wagesta   wageloc
##         0         0         0         0         0         0         0         0
##   mix      ymale
##         0         0
```

The dataset contains 90 counties from North Carolina, all of which is collected in 1988. Out of the 90 counties, 34 are from western NC (out of which 5 is also urban), 21 are from central NC (out of which 1 is also urban), and 8 are considered urban counties. There are no missing values which will make our analysis easier.

```

```

Most of the variables appear to be within a reasonable range, except for *probarr* and *probconv*, which have probability values greater than 1.

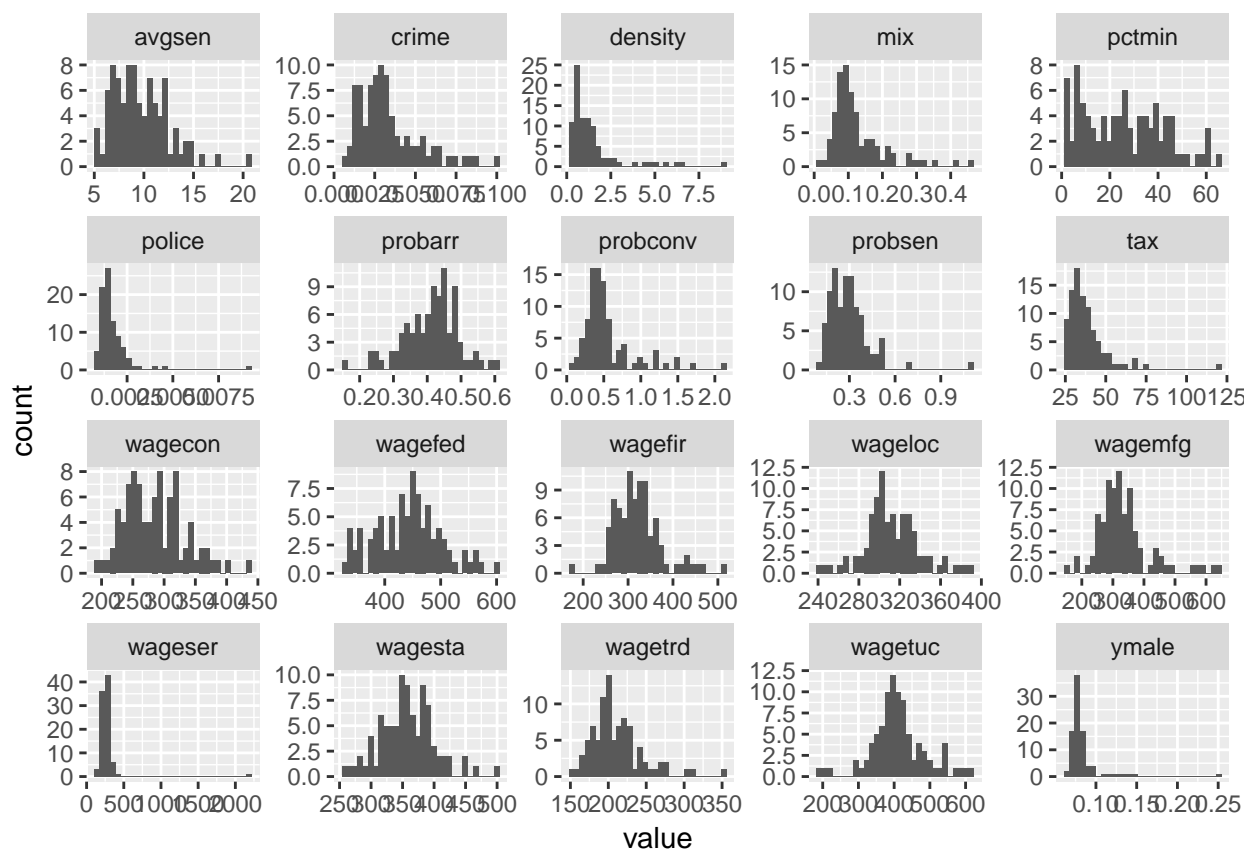

```
# list number of probabilities (probarr, probconv, probsen, mix) that are not in range [0, 1]
c(sum(data$probarr < 0 | 1 < data$probarr), sum(data$probconv < 0 | 1 < data$probconv),
  sum(data$probsen < 0 | 1 < data$probsen), sum(data$mix < 0 | 1 < data$mix))
```

```
## [1] 0 10 1 0
```

probconv and *probsen* contain 10 and 1 datapoints respectively that do not conform to the probability assumption. We will take these outliers into consideration when choosing variables for our models.

We then plot each numeric variable in a histogram to see its sample distribution.

```
# plot every variable except X, county, year, west, central, urban
num.data <- data[!(names(data) %in% c("X", "county", "year", "west", "central", "urban"))]
ggplot(gather(num.data), aes(value)) +
  facet_wrap(~key, scales="free") +
  geom_histogram()
```

```
skewness(num.data)
```

```

```

Most of the sample distributions appear to be positively skewed. When choosing the variables for our regression models, we will consider logarithmic transformations if the interpretations make sense.

From the histograms, we also see several notable outliers. We are under the impression that a county which has an outlier in one variable will likely have an outlier in another variable. For this reason, we have listed counties which have repeated outliers when we iterate through the entire numeric variables.

```
# iterate through each numeric variable and list the outlier counties and their respective frequency
county.ids <- c()
for(var in num.data) {
  var.out <- boxplot.stats(var)$out
  county.ids <- c(county.ids, data[var %in% var.out, ]$county)
}
table(county.ids)
```

```
## county.ids

```

One outlier that is interesting to note is the weekly wage in the service industry for county with id 185, \$2177.10.

```
summary(data$wageser)
```

```
##      Min. 1st Qu.  Median    Mean 3rd Qu.    Max.
## 133.0  229.3   253.1   275.3   277.6  2177.1
```

It is approximately eight times higher than the median. We do not know if the value is inputted incorrectly or if the county in general is making a weekly wage of \$2177.10 in the service industry.

Research Question

James Q. Wilson and George Kelling's "broken windows theory" in 1982 led to a nation-wide movement for stricter crime-fighting policies between the 1980s and 1990s. The theory states:

if the first broken window in a building is not repaired, then people who like breaking windows will assume that no one cares about the building and more windows will be broken. Soon the building will have no windows...

The belief was that by adopting a zero tolerance approach that enforced even the lowest level offenses, crime rates would subsequently go down. While New York City notably enforced this more stringent approach, San Francisco went the opposite direction of less strident law enforcement policies that reduced arrests, prosecutions and incarceration rates. Both sides experienced considerable declines in crime rates. Thus we hope to test the “broken windows theory” for the counties of South Carolina in 1987 and answer the question: Does the conservative approach of deterrence through arrests, incapacitation through imprisonment, harsh sentencing and higher police per capita lead to lower crime rates?

Model 1: only the explanatory variables of key interest

Based on the research question, our initial proposed model will include *crime* as the dependent variable and all variables related to stricter law enforcement policies: *probarr*, *probconv*, *probsen*, *avglen*, and *police* as independent variables. Assuming the “broken windows theory” is valid, we expect generally negative coefficients for all variables.

Given that the histogram of *crime* has a significant positive skew, we noted a log transformation may be suitable since its values are non-zero and positive. The same can be said about the independent variable *police* where its histogram is positively skewed and its values are non-zero and positive.

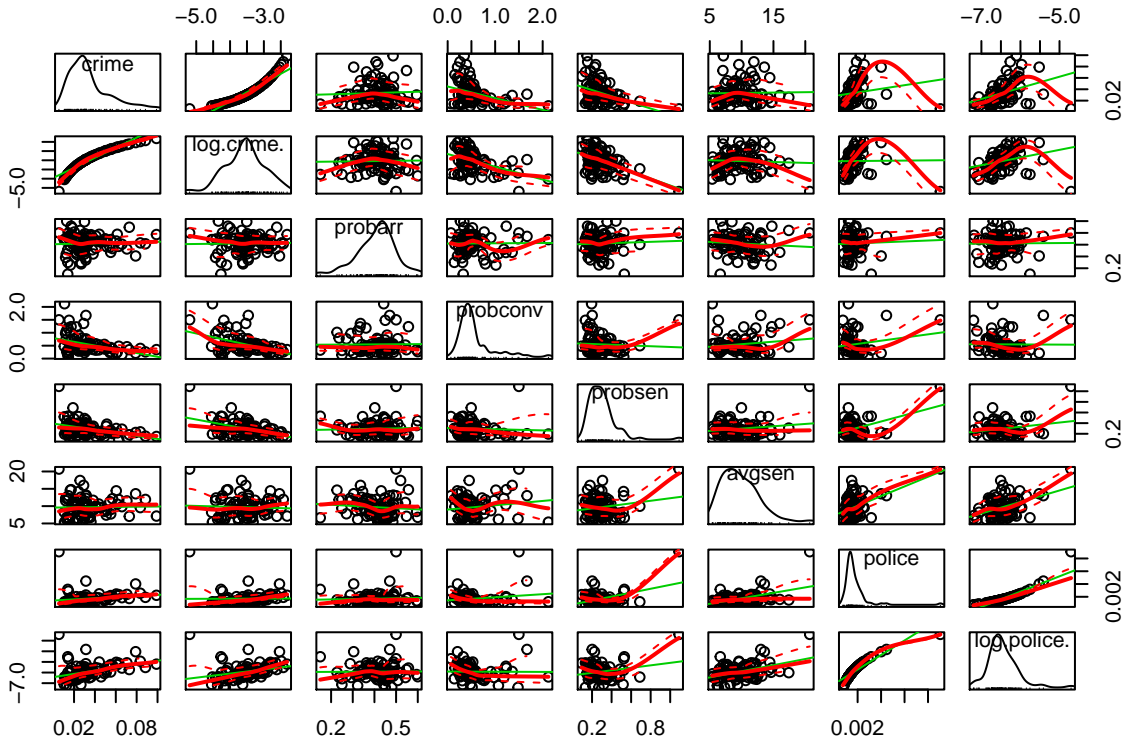

```
# before and after log transformation
hist(data$crime); hist(log(data$crime))
hist(data$police); hist(log(data$police))
```

Though *probarr*, *probconv*, and *probsen* are positively skewed as well, we decided against taking the log of these variables because log transformations can make values between 0 and 1 more extreme. We also kept *avgsen* as is for easier interpretation.

Next, we want to check the relationships between the chosen independent variables and our dependent variable, before and after transformations. We want to ensure that we did not deviate any straight-line relationships between the independent variables and the dependent variable using the transformation.

```
scatterplotMatrix(~ crime + log(crime) +
                  probarr + probconv + probsen + avgsen + police + log(police), data = data)
```

As we can see from the scatterplot matrix, it does not appear that the transformation drastically changed the relationship.

Lastly, based on the exploratory data analysis, we should be careful when considering *probconv* and *probsen* as variables in the model with 10 and 1 datapoints respectively that have probabilities greater than 1. *probconv* is proxied by the ratio of convictions to arrest while *probsen* is proxied by the proportion of total convictions resulting in prison sentences. Although it is unlikely that an individual can be convicted without an arrest or sentenced without a conviction, we cannot rule out the possibility. Both of these variables are important in answering our research question and removing them will result in an omitted variable bias as we will demonstrate below.

Assuming we started out with a base model without *probconv* and *probsen*, we wanted to see what effects *probconv* and *probsen* respectively have on the other explanatory variables when we add them individually to the base model. We looked at the printout of their respective model coefficients to understand the effects. Based on the research question, we expect that higher conviction and higher sentencing will result in lower crime rate. And since the relationship of *probconv* and *probsen* are positive with the other explanatory variables as demonstrated by the correlation matrix, we expect negative bias overall.

```

# demonstrate that probconv and probsen individually have positive relationship
# with the other explanatory variables: probarr, avgsten, police
ind.vars <- subset(data, select= c("probarr", "probconv", "probsen", "avgsten", "police"))
cor(ind.vars, ind.vars)

```

Looking at the coefficients, it does appear that higher conviction (*probconv*) and higher sentencing (*probsen*)

result in lower crime rate (*crime*) as seen by their negative sign in their respective coefficient. We also note that *probconv* and *probsen* are statistically significant when added to the base model. It appears that there is a negative omitted variable bias. For this reason, it would be best to include *probconv* and *probsen* in our Model 1 proposal.

As we will later discuss in section “Discussion of Causality”, if the outliers happen to be a measurement error, it will result in our model being confounded by bias. Although that might be the case, there is also a likelihood that the measurement is valid, and we have demonstrated that not including *probconv* and *probsen* will most likely confound our model with omitted variable bias.

Hence, we propose our first model as follows which contains all explanatory variables of key interest:

$$\log(\text{crime}) = \beta_0 + \beta_1 \cdot \text{probarr} + \beta_2 \cdot \text{probconv} + \beta_3 \cdot \text{probsen} + \beta_4 \cdot \text{avgsen} + \beta_5 \cdot \log(\text{police}) + u$$

We will now run the model and test the validity of the 6 CLM assumptions to ensure that the OLS estimators are consistent, normally distributed, and BLUE (best linear unbiased estimator).

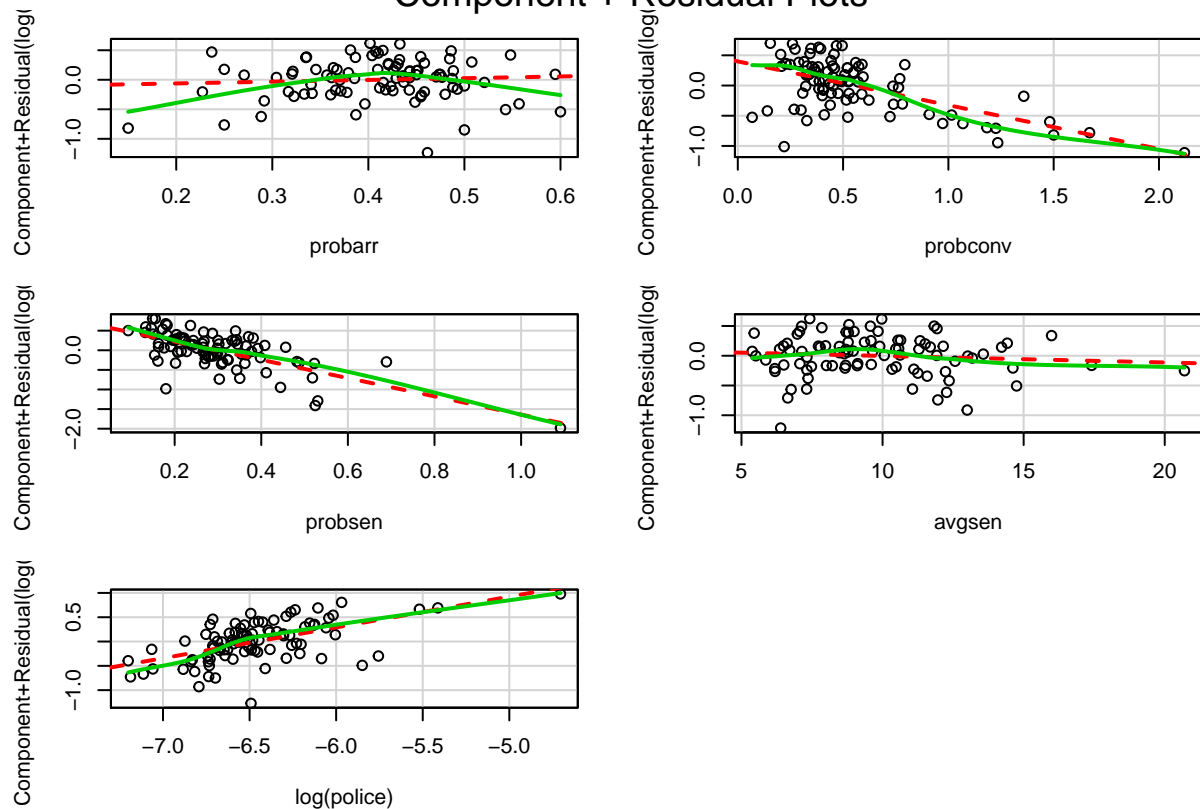

```
m1 <- lm(log(crime) ~ probarr + probconv + probsen + avgsen + log(police), data=data)
```

CLM 1 - A linear model

The model is specified such that the dependent variable is a linear function of the explanatory variables. As shown in the scatterplot matrix above, all of the dependent variables in the model seem to have a linear relationship with the independent variable *log(crime)*. We can verify further the linearity of the relationship using either component+residual plots (also called partial-residual plots) or the CERES plots. We have decided to do the former and note that for the most part, the relationships appear linear.

```
# verify linearity of relationships using component+residual plots  
crPlots(m1)
```

Component + Residual Plots

CLM 2 - Random Sampling

We do not know how the survey is collected. We assume that the variables are representative of the entire population distribution since the counties are subsets of North Carolina. There is nothing we can do to correct this, so we note this as a potential weakness in the analysis.

CLM 3 - Multicollinearity

As a quick test of the multicollinearity condition, we check the correlation of the explanatory variables and their Variance Inflation Factors (VIF):

```
# correlation matrix of explanatory variables
data$log.police <- log(data$police)
cor(data.matrix(subset(data, select=c("probarr", "probconv", "probsen", "avgsen", "police", "log.police"))))
```

| | probarr | probconv | probsen | avgsen | police |
|----------|-------------|--------------|-------------|-------------|------------|
| probarr | 1.0000000 | 0.011022645 | 0.04583324 | -0.09468083 | 0.04820783 |
| probconv | 0.01102265 | 1.0000000 | -0.05579621 | 0.15585232 | 0.17186514 |

```

```
## probsen      0.216243619
## avgsen       0.437293263
## police       0.905773321
## log.police   1.000000000
```

```
# verify VIFs are less than 10
vif(m1)
```

```
##      probarr      probconv      probsen      avgsen log(police)
##      1.016889      1.039388      1.068228      1.310152      1.277425
```

The explanatory variables (*probarr*, *probconv*, *prbpis*, *avgsen*, *log.police*) are not perfectly correlated and the VIFs are low (i.e. less than 10), so there is no perfect multicollinearity of the independent variables.

CLM 4 – Zero-Conditional Mean

To see whether there is a zero-conditional mean across all *x*'s, we will plot the residuals against the fitted values.

```
# plot residual vs fitted plot & residual vs leverage plot
plot(m1, which=c(1, 5))
```

The residual vs fitted plot indicates little evidence that the zero-conditional mean assumption does not hold since the red spline line remains close to zero despite its slight dip and rise at both ends due to fewer observations.

Furthermore, it does not appear that the outliers have undue influence on the model fit. Based on the residual vs leverage plot, none of the outliers have a leverage that exceeds a Cook's distance of 1 on the regression model.

We have also taken a look at the covariances of the independent variables with the residuals to see if the variables we chose are likely to be exogenous.

```
# calculate the covariance for each independent variables with the model's residuals
lapply(subset(data, select=c("probarr", "probconv", "probsen", "avgsen", "log.police")),
       function(var) cov(var, m1$residuals))
```

```
## $probarr
## [1] 0.000000000000000008087166
##
## $probconv
## [1] 0.000000000000000003500816
##
```

The Score-test also validates this assumption. Since the p-value is statistically not significant, we cannot reject the null hypothesis of constant error variance.

For this reason, the assumption of homoskedasticity is met.

CLM 6 – Normality of residuals

To determine whether there is normality of the residuals, we looked at the histogram and the Q-Q plot of the residuals and visually observe whether there is normality.

```
# normality of standard residuals
rstnd = rstandard(m1)
hist(rstnd, main="Histogram standard residuals", breaks=50, freq=FALSE)
curve(dnorm(x, mean=0, sd=sd(rstnd)), col="red", lwd=2, add=TRUE)
# normality of studentized residuals
rstud = rstudent(m1)
hist(rstud, main="Histogram studentized residuals", breaks=50, freq=FALSE)
curve(dnorm(x, mean=0, sd=1), col="red", lwd=2, add=TRUE)
# Q-Q plot standard residuals
qqPlot(rstnd, distribution="norm", pch=20, main="Q-Q Plot standard residuals")
qqline(rstnd, col="red", lwd=2)
# Q-Q plot studentized residuals
qqPlot(rstud, distribution="norm", pch=20, main="Q-Q Plot studentized residuals")
qqline(rstud, col="red", lwd=2)
```

The histograms appear to be negatively skewed. The Q-Q plots further supports it with a fat negative tail.

```
#check sample size for model 1
nobs(m1)
```

```
## [1] 90
```

Although the assumption is not met, given the substantial sample size, we can be confident that due to OLS asymptotics the distribution of the residuals will be approximately normal.

Since all six assumptions of the Classical Linear Model are met, we can assume that the OLS estimators are consistent, normally distributed and BLUE.

Model 2

One model that includes key explanatory variables and only covariates that you believe increase the accuracy of your results without introducing bias (for example, you should not include outcome variables that will absorb some of the causal effect you are interested in). This model should strike a balance between accuracy and parsimony and reflect your best understanding of the determinants of crime.

Model 3: most, if not all, other covariates

Adding arbitrary variables uses up valuable degrees of freedom which increases the standard error which in turn reduces the precision of this estimate. This effect is especially pronounced in small sample size.

One model that includes the previous covariates, and most, if not all, other covariates. A key purpose of this model is to demonstrate the robustness of your results to model specification.

```
# EDA for variables that aren't in model 1 or 2
summary(data[(names(data) %in% c("west", "central", "urban", "wagecon", "wagetuc", "wagetr", "wagefir"

```

```
## Median :307.6
## Mean   :312.3
## 3rd Qu.:328.8
## Max.   :388.1
```

Looking at the summary, every variable seems to be in an expected range except for the outlier 2177.1 in *wageser*.

```
# Look into wageser with an unusual max of 2177.1
boxplot(data$wageser)
```

2177.1 is clearly an outlier in the data and could be possibly due to a measurement error. In this case, we decide not to include this *wageser* to avoid confounding bias caused by potentially inaccurate data.

Moreover, let's look at how *west* and *central* distribute in the sample

```
unique(cbind(data$west, data$central))
```

```
##      [,1] [,2]
## [1,]    1    0
## [2,]    0    1
## [3,]    0    0
```

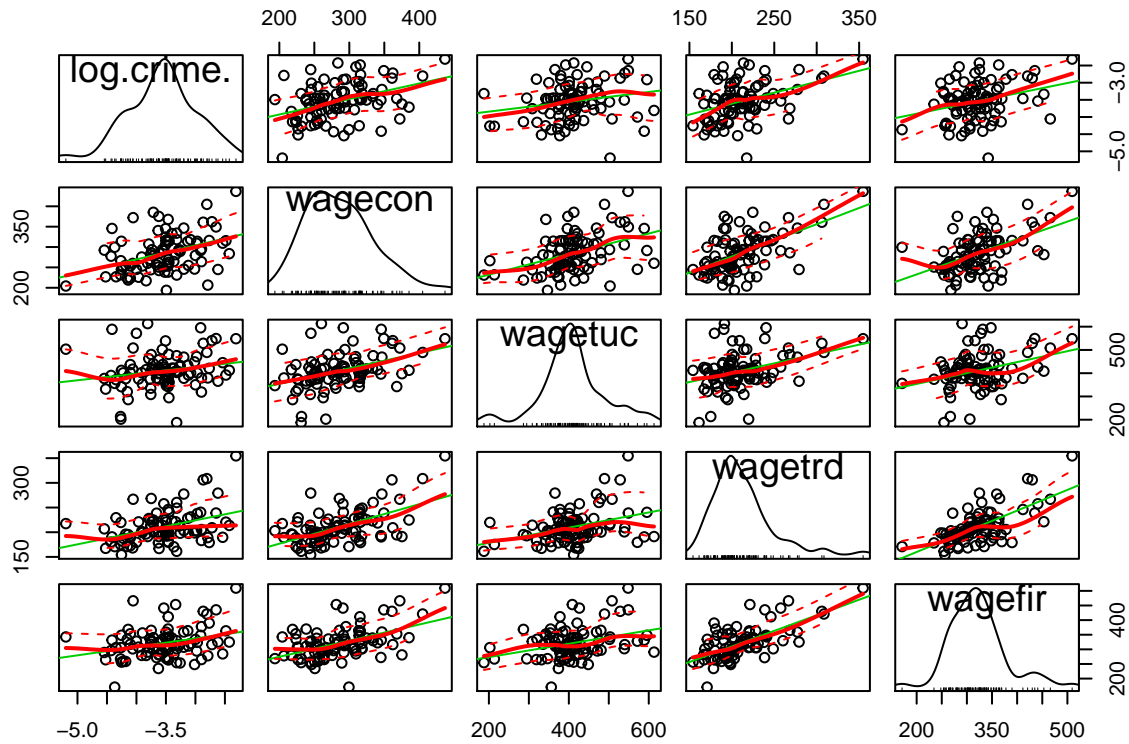

Note that although we don't have any counties that are both in west and central, as expected, we see some counties that neither in west or central. In order to consider the effect on different regions, we will need to use both indicator variables in our model.

Out of all the variables that aren't included in Model 1 or Model 2, we have decided to include: 1) *west* & *central*, as indicator variables, to control for the regional effect on crime rate 2) *urban*, as an indicator variable, to control for the non-density impact of urbanization on crime rate 3) *wagecon*, *wagetuc*, *wagetrd*,

wagefir, *wageser*, *wagemfg*, *wagefed*, *wagesta*, *wageloc* to control for the effects of wages in different industries have on our crime rate 4) *pctmin* and *ymale* to control for the demographic effect on crime rate

Now let's look the relationship between the selected variables and our dependent variable *log(crime)*

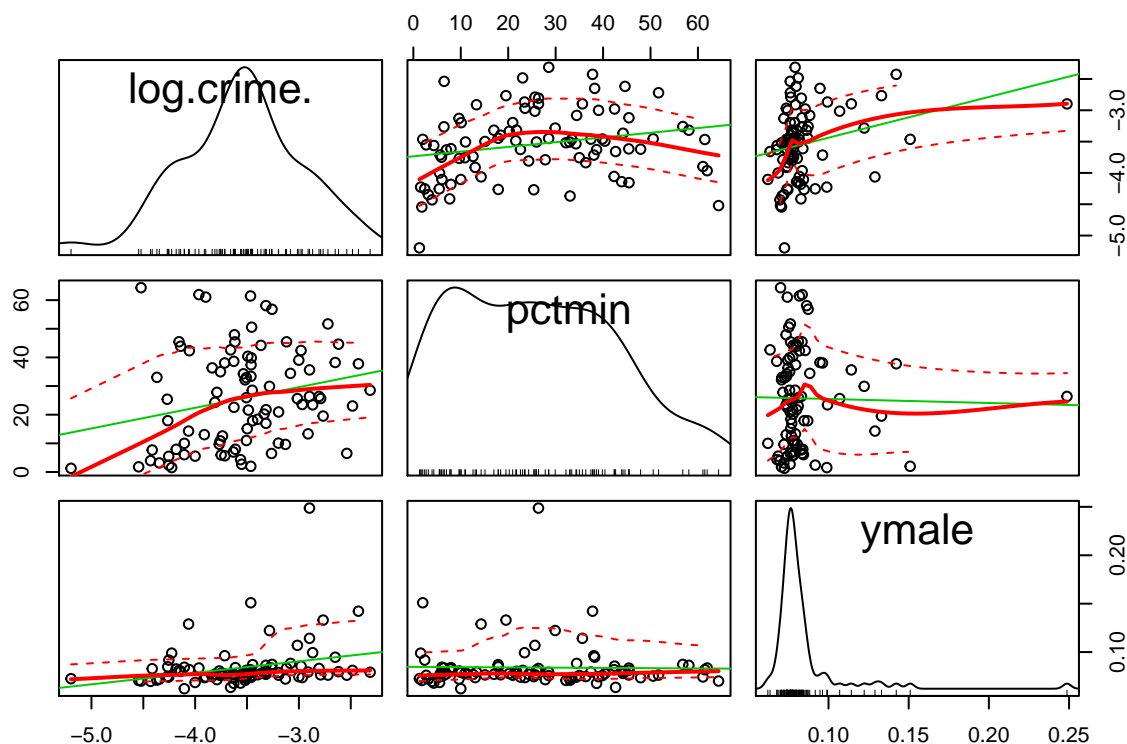

```
scatterplotMatrix(~ log(crime) + wagecon + wagetuc + wagetrd + wagefir, data = data)
```

```
scatterplotMatrix(~ log(crime) + wagemfg + wagefed + wagesta + wageloc, data = data)
```

```
scatterplotMatrix(~ log(crime) + pctmin + ymale, data = data)
```

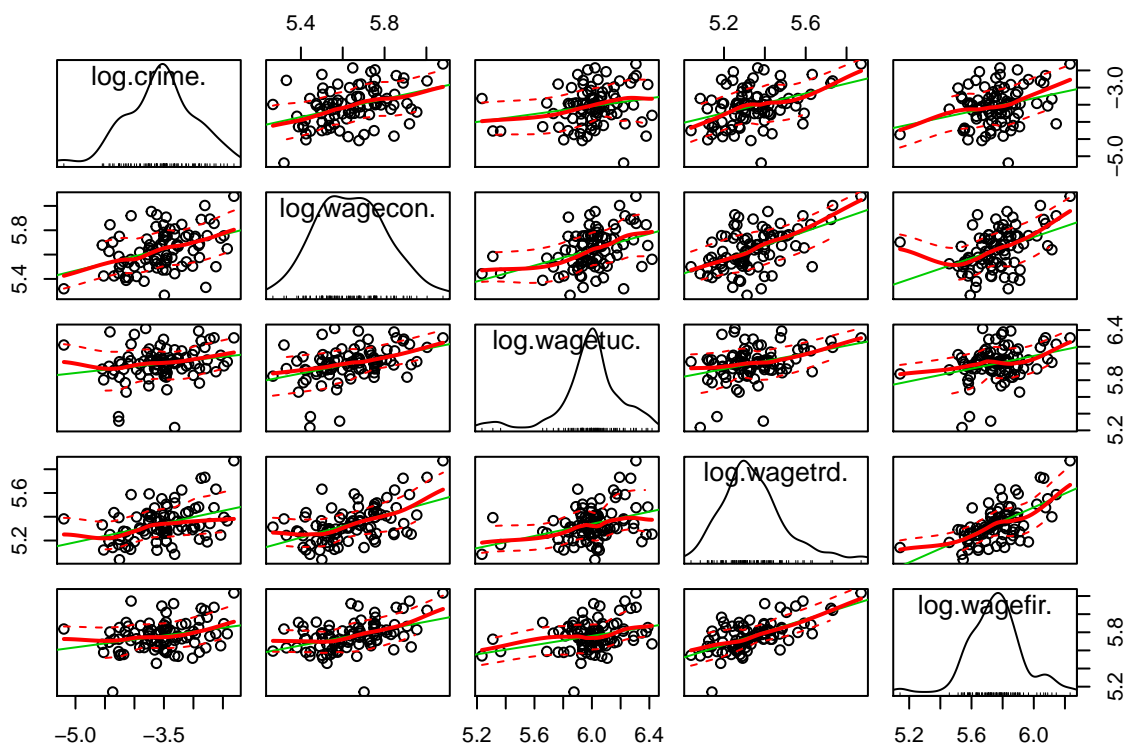

None of the variables shows strong evidence of non-linear relationship with the dependent variable $\log(\text{crime})$.

We notice that the distributions for the variables wagecon , wagetrd , wagefir , wagemfg , wagesta , and wageloc are positively skewed, since they are all positive values, we can apply log transformations to all of them. For the ease of the interpretation of the model, we apply log transformation to the other wage related variable wagetuc as well.

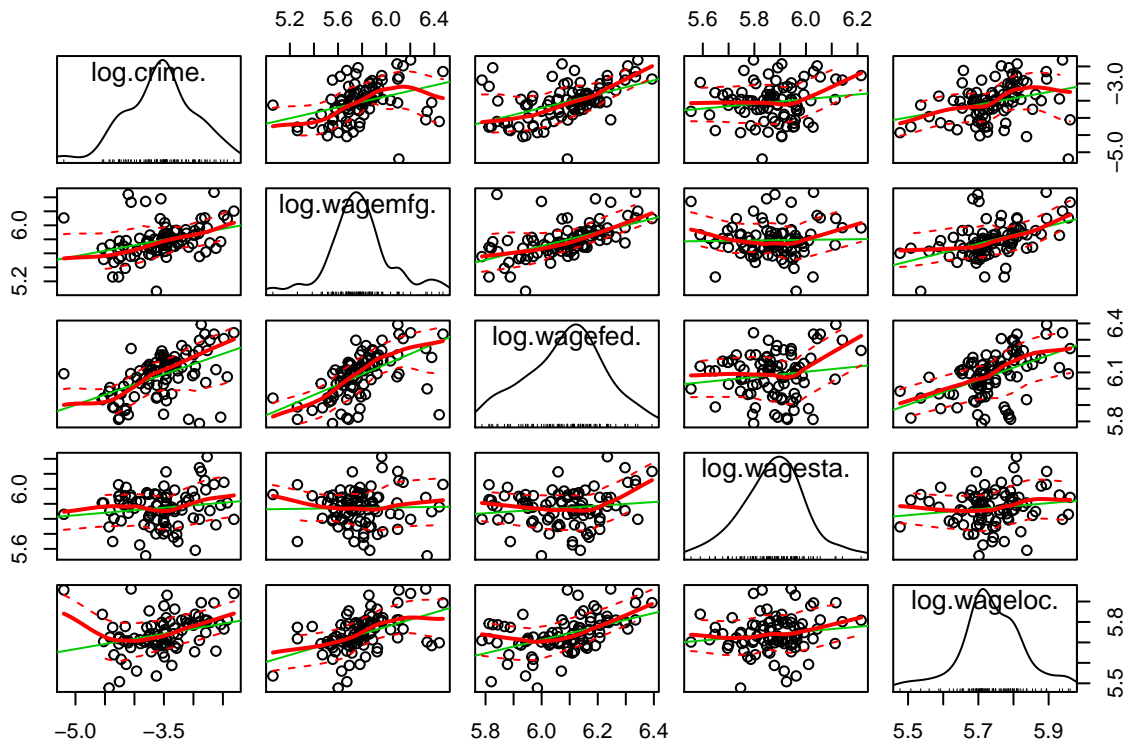

Although ymale is also positively skewed and could benefit from a log transformation in terms of normality, it's hard to interpret the slope parameter of its log transformation. Hence, we decided to leave it as it is.

Let's double check the linearity of the relationship between our transformed variables and our dependent variable $\log(\text{crime})$

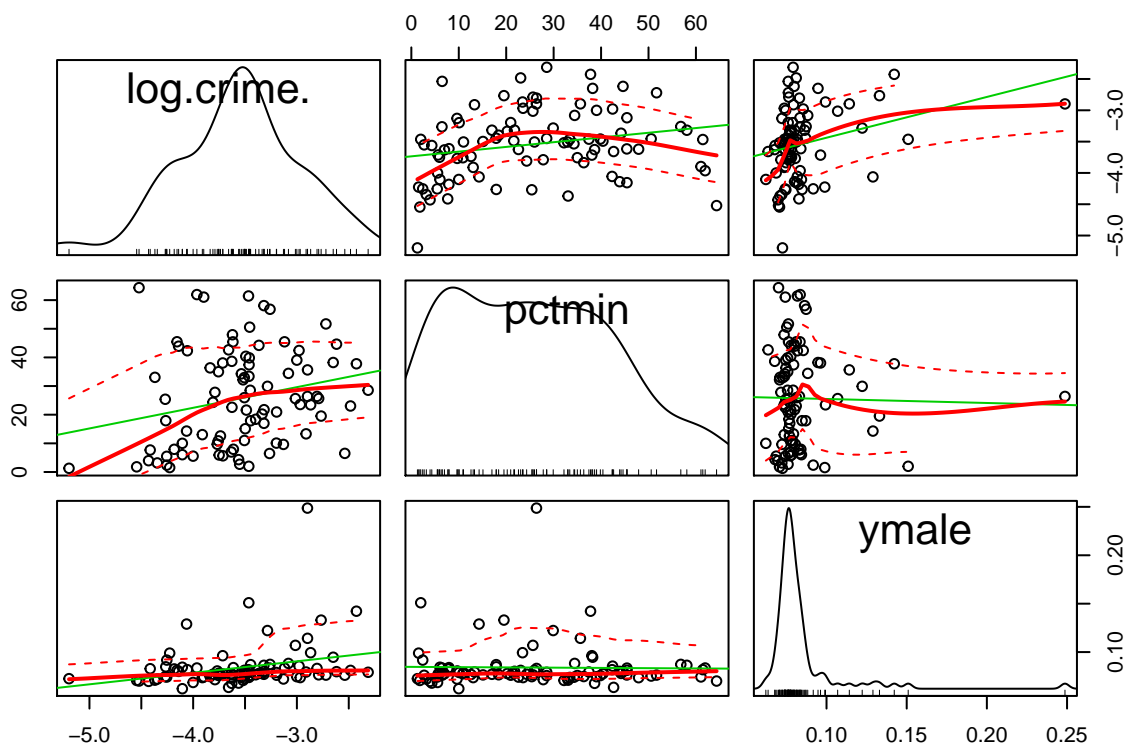

```
scatterplotMatrix(~ log(crime) + log(wagecon) + log(wagetuc) + log(wagetrd) + log(wagefir), data = data)
```

```
scatterplotMatrix(~ log(crime) + log(wagemfg) + log(wagefed) + log(wagesta) + log(wageloc), data = data)
```

```
scatterplotMatrix(~ log(crime) + pctmin + ymale, data = data)
```

We didn't see any strong violation against the linearity of the relationships. Hence, we will propose the following model:

```
m3 <- lm(log(crime) ~ probarr + probconv + probsen + avgsen + log(police) + log(density) + log(tax) + m
plot(m3)
```

Fitted values
 $\ln(\log(\text{crime})) \sim \text{probarr} + \text{probconv} + \text{probsen} + \text{avg sen} + \log(\text{police}) + \log(d \dots$

Theoretical Quantiles

$\ln(\log(\text{crime})) \sim \text{probarr} + \text{probconv} + \text{probsen} + \text{avg sen} + \log(\text{police}) + \log(d \dots$

$\text{lm}(\log(\text{crime}) \sim \text{probarr} + \text{probconv} + \text{probsen} + \text{avgsen} + \log(\text{police}) + \log(\text{density}))$

```
bptest(m3)
```

```
##
## studentized Breusch-Pagan test
##
## data: m3
## BP = 41.375, df = 20, p-value = 0.003333
```

Similar to Model 1, Model 3 shows 1) no strong violation of zero-conditional mean, according to the Residuals vs Fitted plot, 2) has no outlier with large influence and 3) shows skewedness in the QQ plot for the residuals. However, Model 3 shows a violation of homoskedasticity according to both the Residuals vs Fitted and the Scale-Location plots.

In response, just like what we normally would have done to be conservative, we will use the heteroskedasticity-robust standard errors for the hypothesis tests on the slope parameters.

One typical concern when including variables that tend to be highly correlated, like wages, is that the multi-collinearity will inflate the variance of the OLS estimated parameters. And to investigate this, we compute the variance inflation factors (vif) of each variable in the model:

```
vif(m3)
```

```
##      probarr      probconv      probsen      avgsen  log(police)
##      1.194093      1.622417      1.893087      1.659673      2.581225
## log(density)  log(tax)          mix          west      central
##      4.776603      2.074658      2.042717      1.733676      1.572025
##      urban log(wagecon) log(wagetuc) log(wagetrd) log(wagefir)
##      2.569216      2.135744      1.707301      3.060257      2.596568
## log(wagemfg) log(wagefed) log(wagesta) log(wageloc)      ymale
```

```
##      2.262547      3.045837      1.653602      2.258130      1.536937
```

Looking at the variance inflation factors, we don't see any variable with high (>10) vif, meaning that we don't have high multi-collinearity in our model.

Next, we can use the heteroskedasticity-robust standard errors to perform t-tests on our estimated parameters:

```
#compute standard errors for model 3 for regression table
(se.m3 = sqrt(diag(vcovHC(m3))))
```

```
## (Intercept)      probarr      probconv      probsen      avgsen

## Note:                               *p<0.05; **p<0.01; ***p<0.001

```

According to the hypothesis tests using the heteroskedasticity-robust standard errors, we can see that variables *probconv*, *probsen*, *west*, *central* show strong statistical significance (p-value < 0.001), same with *log(density)* (p-value < 0.01) and *log(police)* (p-value < 0.05).

Moreover, to interpret the estimated parameters for: 1) *probconv*: keeping all other variables constant, a 0.1 increase in *probconv* results in a 5.23% decrease in crime rate 2) *probsen*: keeping all other variables constant, a 0.1 increase in *probsen* results in a 14.56% decrease in crime rate 3) *west*: keeping all other variables constant, being in west region decreases crime rate by 29.4% 4) *central*: keeping all other variables constant,

being in central region decreases crime rate by 51.5% 5) $\log(density)$: keeping all other variables constant, an 1% increase in density increases crime rate by 0.18% 6) $\log(police)$: keeping all other variables constant, an 1% increase in police per capita increases crime rate by 0.49%

And from this, *probconv*, *probsen*, *west*, *central* show strong practical significance.

Summary of Models

Discussion of Causality

Conclusion

TODO: These are notes for policy suggestions

Read more on <http://lawenforcementleaders.org/wp-content/uploads/2017/10/Law-Enforcement-Letter-to-President-Trump-and-Attorney-General-Sessions.pdf>

this effort is undercut by a diffuse focus. Attorney General Sessions' regular statements encouraging law enforcement to focus on drug and nonviolent offenders divert officers away from that vital mission. Law enforcement resources are limited. Focusing on low-level non-violent offenders means less time to stop and bring to justice the most dangerous offenders.

From our experience, we do not believe that always seeking the longest possible sentence will make our country safer. More than 25 percent of the Justice Department's budget is consumed by federal prisons.[iv] Every unnecessary dollar spent on prisons is a dollar not spent on policing. And often, the best way to prevent recidivism is through treatment, not prison. Responsibly reducing incarceration will free funding and time for our officers to focus on targeting and preventing violent crime, making our streets safer.[v]
